

## Application note

### Characterizing concentrated colloidal suspensions by static light scattering (SLS)

Prepared by Ian D. Block at LS Instruments, June 2010

#### Introduction

Static light scattering (SLS) is a technique in which laser light scattered from a sample is measured as a function of scattering angle. The angular response is in general complex and is a function of dipole emission profiles and of the interference of light scattered from refractive index boundaries of the particles. These contributions to the overall angular-dependent scattering profile provide a wealth of information on particle size and shape, as well as structure and interactions in the sample. In this application note we focus on measuring the particle form factor of a concentrated colloidal suspension from which we extract the size (radius of gyration,  $R_g$ ) and size distribution (polydispersity).

Modelling SLS data and extracting accurate particle and structure information mandates the measurement and analysis of single scattering events. SLS measurements therefore traditionally require extreme sample dilution in order to limit the influence of multiple scattering. **However, the 3D cross-correlation technique eliminates this necessity and opens the door to measurement of extremely turbid and even opaque samples.**

#### SLS measurements for a dilute sample

In order to provide a reference for subsequent turbid measurements, SLS data was first gathered for a very dilute suspension of 430 nm polystyrene particles in deionized water ( $3 \times 10^{-7}$  w/w, >99% transmission) over a range of scattering angles. The data shown in Fig. 1 were fit using the Mie scattering model (MiePlot, UK) and a visual best-fit with particle refractive index fixed at  $n = 1.58$  gives  $R_g = 210$  nm and 1% polydispersity, in excellent agreement with the nanoparticle product specifications.

**Figure 1:** SLS data and Mie fit for a dilute sample ( $3 \times 10^{-7}$  w/w, >99% transmission) of 430 nm polystyrene particles in water.

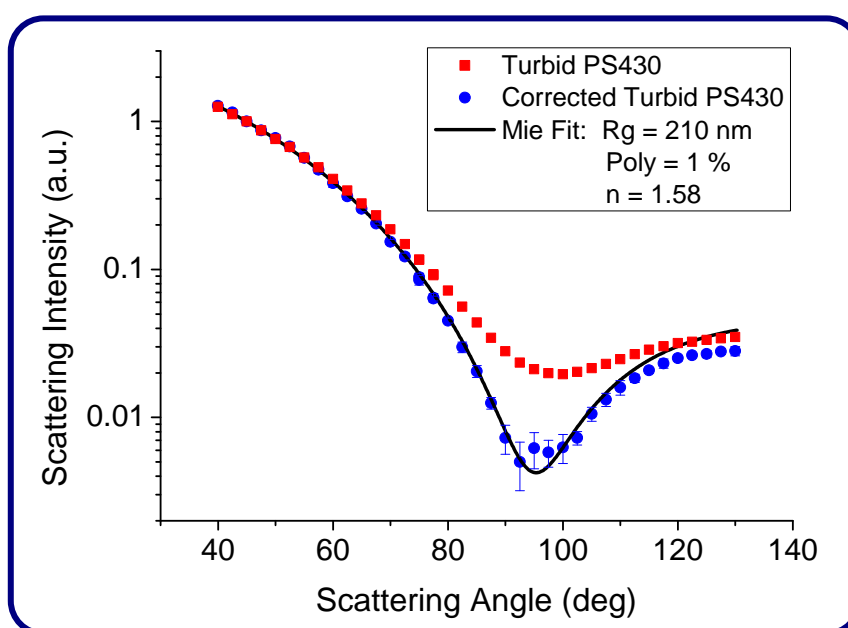

## SLS measurements for a turbid sample

With the 3D DLS from LS Instruments, accurate static light scattering measurements in concentrated, highly scattering turbid samples can be performed. However, the undesired contributions from multiply scattered light have to be subtracted from the measured scattered intensity  $I_s$ . This can be accomplished by performing a combined static and dynamic cross-correlation experiment. In the static measurement,  $I_s$  is determined as a function of scattering angle  $\theta$ , while the dynamic measurement gives the part of  $I_s$  which is only singly scattered via the intercept  $\beta_{12}(\theta)$  of the cross-correlation function [1]. In the measurement, the reduced intercept  $\beta_{12}(\theta)$  is normalized to  $\beta_{12}^{\max}(\theta)$ , where  $\beta_{12}^{\max}(\theta)$  is the intercept measured with a diluted sample without multiple scattering contributions. This automatically corrects for any weak angular dependence of the intercept due to the geometry of the overlap volume and the alignment of the instrument.

The corrected singly scattered intensity as a function of the scattering angle can be calculated as:

$$I_c = \sqrt{\frac{\beta_{12}(\theta)}{\beta_{12}^{\max}(\theta)}} \cdot I_s \quad (1)$$

Fig. 2 displays the scattered intensity (red squares) measured for a sample of the same 430 nm polystyrene particles but at significantly increased concentration ( $5 \times 10^{-5}$  w/w), rendering the sample highly turbid (46% transmission). The high degree of multiple scattering for this sample significantly washes out the form factor minimum, and without correction would lead to dramatic errors in estimating sample polydispersity (of nearly an order of magnitude) and mean size. However, by using DLS cross-correlation measurements taken in conjunction with the SLS data and applying Eqn. (1), we accurately recover the true particle form factor (blue circles) by extracting only the single-scattering information. This technique becomes even more important when finer features become hidden by multiple scattering that for example, reveal interaction potentials in the sample.

**Figure 2:** Corrected and uncorrected SLS data along with a Mie fit for a turbid sample of 430 nm polystyrene particles in water ( $5 \times 10^{-5}$  w/w, 46% transmission).
